**Abstract-** In this study, carbon quantum dots (CQDs) was prepared via a facile hydrothermal method. The objective for this study is to assess the performance of CQDs in photocatalytic degradation activity of methyl orange (MO) under artificial visible light source. For that reason, the prepared photocatalyst undergo further characterization by scanning electron microscope (SEM), energy dispersive X-ray spectroscopy (EDX) and UV-Vis spectrophotometer (UV-VIS) to verify the morphology structure of the photocatalyst, elemental composition as well as the absorbance intensity, respectively. The results indicates that the prepared photocatalyst possess irregular porous shape with nanometre (nm) dimensions that can escalate the surface area for photocatalytic degradation activity. The elements of the photocatalyst mainly consist of carbon and oxygen as the major constituents in which necessary for photocatalytic activity with intense peak of absorbance intensity. The prepared CQDs also shows an excellent photocatalytic performance over the MO with degradation rate of 68.9% within 120 minutes.

**Keywords-** CQDs, hydrothermal, methyl orange, photocatalytic degradation, watermelon rinds

### I. INTRODUCTION

The development of utilization of synthetic dyes contributes many negative impacts on human well-being as well as the aquatic organisms when directly dispense out to the environment. The dyes comprise of toxic and complex components, which can influence unfavorable color changes of the water due to their slow degradation rate. Furthermore, the unpleasant effect not only from aesthetic point of view, yet in addition from decreasing in sunlight penetration that reducing the activity of photosynthesis [1,2]. Dyes are widely used in industries like textile, food, cosmetics, plastics, printings and paper to color their products. Annually, there are about 100,000 types of synthetic dyes with more than 70,000 tons of production from the associated industries in which 15- 20% of it lost and carried away as wastewater [2,3]. Methyl orange ( $C_{14}H_{14}N_3NaO_3S$ ) is one of the anionic dyes that extensively used in the associated industries and concerning to its amount and harmful effect, it is important to treat the dye components before discharging into the water body [2-4].

One of the promising methods in handling the dye wastewater other than reverse osmosis, electrocoagulation, electrochemical oxidation, membrane filtration, ozonation and adsorption is photocatalysis. Photocatalysis is a process where light and catalyst are simultaneously utilized in order to support and speed up the chemical reaction [5]. Photocatalysis process has showing significant advantages over the available competing process nowadays in terms of complete mineralization, no waste disposal, low cost and necessity need of mild temperature and pressure condition [5,6]. In this process, when photocatalyst is irradiated with sufficient energy corresponding to the band gap, electron transfer may occur. The capability of electron transfer to occur within the photocatalyst makes it possible to be utilized as a trigger to start redox reaction with the substrate. This redox reaction take action on the photodegradation of organic compounds inclusive the dye

molecules and convert them into basic compounds such as CO<sub>2</sub>, H<sub>2</sub>O and mineral acids [4,5]. Over the past decades, CQDs turned up to be as an attractive materials for photocatalysis applications since it is first discovered in 2004, that firstly disclosed by accident when refining carbon nanotubes fabricated by arc- discharge method [7,8]. CQDs which embarked their way as a class of carbon-based nanomaterials over the past decade can be seen have quasi- spherical in shape, discrete and less than 10 nm in size. Obviously, due to their unique characteristics they had attracted huge interest in many fields such as bioimaging, biosensing, electrocatalysis, photocatalysis and nanomedicine [9,10]. CQDs, primarily consist of amorphous carbon together with nanocrystalline regions of sp<sup>2</sup>-hybridized graphitic carbon. Recognizably from many other carbon nanomaterials like carbon nanotubes, graphene oxide and graphene quantum dots, CQDs can be synthesized effortlessly and economically using low- cost and sustainable source of biomass such as watermelon rinds, hair and even cow manure [11]. As a result, variety of synthesizing approaches for the preparation of CQDs were developed. In past few years, several methods involve in the synthesis of CQDs including laser ablation [12,13], arc discharge [14], pyrolysis [15], hydrothermal treatment[16,17] and microwave irradiation [18–20]. Regardless of all that, although the above mentioned procedures excluding the hydrothermal, were successful in producing the CQDs, yet they clearly suffer some difficulties because most of the methods required tedious process with several steps, harsh chemical reaction, complex instrumental setup, limited spectral efficiency and low product yield which restrict their wide applications [21,22].

Since discovery, CQDs outbreak many fascinating qualities which settle them as potential replacement for conventional semiconductor quantum dots in enhancing photocatalytic degradation. Mainly, they possess a strong photoluminescence (PL) which can be tuned and controlled by the nanoparticles' size. The formation of thin insulating capping layer by surface passivation can assist to further improve the fluorescence intensity of the CQDs. Moreover, since CQDs are carbon based materials, they may as well own oxygenated groups, in which their surfaces can be easily functionalized with the organic molecules. Thus, various heteroatoms can be introducing to them and be useful in tailoring their wavelength emission and consequently their applicability [23]. CQDs are highly soluble in H<sub>2</sub>O with desirable and adjustable hydrophilicity. CQDs possess two additional and vital characteristics; low cytotoxicity and excellent biocompatibility that exhibit them superior compared to conventional semiconducting quantum dots and equipped them with the potential of biological use [8,16,23].

The utilization of watermelon rinds (WMR) acquire from the agricultural wastes as carbon source has aroused the interest and enthusiasm of researchers as conducted studies by Han and coworkers [15],Jawad et.al [24] and Jimoh et.al [25] because it offers both low cost of carbon source and address the agricultural waste problem altogether. Watermelon (*Citrullus lanatus*) being an exceptionally well known and notable as a non-seasonal fruit in Malaysia that categorized as a major fruits by the Ministry of Agriculture and Agro-based Industry, with an average production rate around 154,416 tones [24]. The freshening and thirst- quenching red flesh with pleasant smell and taste make the watermelon very popular in making juice and even desserts. In spite of its popularity, the outer WMR is treated as waste that not valuable in daily life. WMR contain protein, carotenoids, cellulose, citrulline, pectin and flavonoids [24,26,27] with abundant of various surface functional groups such as carboxyl, hydroxyl and amine that can easily draw the cationic ions and renders them a potential candidates in water and wastewater treatment. In addition, because of antioxidant activity of citrulline it produce hydroxyl radicals strong oxidizing agent which is suitable for degradation process[28]. Moreover, many researchers speculate that flavonoids in the WMR are potential scavenger of hydroxyl that can be used for photocatalytic activity [24,29,30].

The purpose of this present study is to explore the potentiality of CQDs in photocatalytic degradation for color removal of aqueous solution containing MO dye under artificial visible light.

This study will start with the production routes of CQDs, followed by a brief look on the crystalline and electronic structure of the photocatalyst as well as the photocatalyst optical properties. Then, the vital contribution of CQDs as an active component in artificial visible light photocatalysis will be analyzed in detail, based on the properties that have been examined.

## II. MATERIALS AND METHODS

### 2.1 Materials

Watermelon rinds were collected from Universiti Malaysia Pahang (UMP) Cafeteria and used as source of carbon. Ethanol ( $C_2H_6O$ , 95%), dichloromethane ( $CH_2Cl_2$ , 99.8%) and acetone [ $(CH_3)_2CO$ , 99%] were purchased from Sigma Aldrich Chemical Co. All the purchased chemicals were analytical grade and used without further purification. Distilled water was used for sample preparation.

### 2.2 Preparation of CQDs

CQDs was synthesized using the mixture of fruit waste and ethanol via hydrothermal treatment. Watermelon rinds were collected from UMP Cafeteria. The watermelon rinds then washed thoroughly with distilled water and drained to remove excess water. The watermelon rinds were cut into smaller pieces and grinded into fine paste using a blender and filter using 0.5mm sieve. 40 ml of watermelon rinds juice was mixed with 30 ml ethanol under vigorous stirring for 5 minutes. Then, the mixture was poured into Teflon-lined-stainless steel autoclave and heated at constant temperature of  $120^\circ C$  for 150 minutes in oven. The resulted dark brown solution is washed with dichloromethane ( $CH_2Cl_2$ ) and centrifuged at 3000 rpm for separation of less fluorescence deposit. Excess acetone ( $(CH_3)_2CO$ ) is added to upper parts of solution and centrifuged at 6000 rpm to obtain highly fluorescent CQDs of size ranging from 1.5 – 4.5 nm [21].

### 2.3 Characterization

The morphologies of samples were examined by a Scanning Electron Microscope (SEM, HITACHI TABLETOP TM3030 PLUS). The images were taken at an accelerating voltage of 15 kV. The energy dispersive X-ray spectroscopy (EDX) (Hitachi Model, TM3030 Plus) were analyzed to determine the occurrences of the important elements present in the prepared samples. The sample were acquired at 30 seconds acquisition time with 15kV of accelerating voltage. The visible light absorption spectrum (300-900nm) of the prepared photocatalyst was certified by UV-Vis analysis (UV- 2600, SHIMADZU) and quartz cell (10 mm path length).

### 2.4 Measurement of photocatalytic activity

The photocatalytic activity was carried out by a self-made reactor equipped with a Halogen lamp (500 W) with  $<420$  nm UV cut- off filter to stimulate the irradiation and light intensity. The photocatalytic activity of CQDs were conducted by evaluating the removal rate of methyl orange (MO). 0.1g of CQDs was prepared and dissolved in 100mL of MO solution (5ppm). This mixture was kept under magnetic stirring for 1 hour in dark to achieve the adsorption equilibrium before light irradiation. After 1 hour, 3ml of the solution was taken out to evaluate the concentration. After that, 500W halogen lamp that positioned above 11 cm from the surface of the MO solution was switch on [9,12,31]. The reaction was performed for 120 min and the solutions were collected for every 20 min. The absorbance for both solutions were determined by measure out the absorbance using a UV-Vis Spectrophotometer (UV-1800, SHIMADZU) in the range between 200nm to 1100 nm. The degradation rate of dyes can be calculated using the following equation below:

$$\text{Degradation rate, \%} = \frac{C_0 - C}{C_0} \times 100\%$$

Where,

$C_0$  = Initial concentration of pollutant

$C$  = Final concentration of pollutant

### III. RESULTS AND DISCUSSION

#### 3.1 CQDs Characterization

##### 3.1.1 SEM Analysis

The identification of the structure and morphology of CQDs was carried out through SEM. As depicted in **Figure 1**, based on the SEM analysis of the CQDs revealed that nanostructured of CQDs was not fully dispersed in water and the agglomeration occur due to the long period of storage before analysis was carried out. This causes the formation of irregular porous shapes of CQD dots with nanometer dimension of particles size. However, the condition was not retain after sonication process. Sonication process is conducted for evenly dispersing the nanoparticles in liquid to get a better result of the nanoparticles structure.

**Figure 1:** Image of CQDs from SEM analysis

##### 3.1.2 EDX Analysis

At the same time, EDX spectrum of CQDs that illustrated in **Figure 2**, unveil the overall elements that presented in CQDs. They consist of C, O, Na, K, Cl and Au. Each peak produced correspond to a particular element present in CQDs and was distributed during the preparation of the sample. The primary constituents of the CQDs photocatalyst comprise of C (51.57 wt. %) and O (34.50 wt. %) that can be observed clearly in it which also indicating the presence of oxygenic groups such as carboxyl,

hydroxyl or carboxyl which can be further confirm through XPS. The occurrences of these elements is corresponding with study carried out by Niranjan and Bibekananda using banana juice as the carbon precursor. The value is slightly higher which is 63.39:35.69 and 70.07:29.61 of C to O ratios respectively [32]. The existence of these oxygenic group is expected to enhance the photocatalytic activity. Meanwhile, the minority elements of the CQDs photocatalyst include Na, K, Cl and Au which are less than 10 wt. %.

**Figure 2:** EDX image of CQDs

### 3.1.3 UV-VIS Analysis

The remarkable optical properties of CQDs are viewed as one of the essential factor that will influence the uses of CQDs. The UV-Vis absorption spectrum of CQDs solution in the range of 300nm to 900nm was exhibited in the **Figure 3**, which display only one intense absorption peak in the UV region at about 318nm, which correlated to  $n-\pi^*$  transitions of C=O bonds in CQDs with a tail elongate to the visible range and all the result are in agreement with the previously reported studies [8,33,34]. At the same time, since one of the beneficial roles of CQDs is extending the optical absorption range of photocatalyst, this optical characteristic lead to bandgap narrowing of the semiconductor when incorporate with CQDs owing to the chemical bonding that will be formed between the semiconductor and CQDs which in result can extend the light absorption range in enhancing photocatalytic degradation.

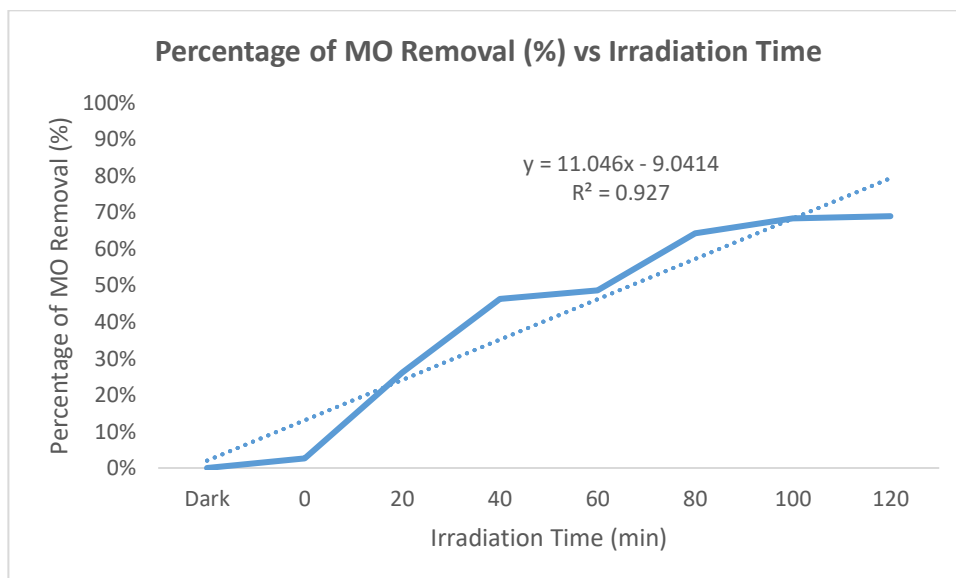

**Figure 3:** Absorbance spectrum of CQDs

### 3.2 Photocatalytic activity

To evaluate the performance of photocatalytic activity under the irradiation of visible light, MO was used as target pollutant. As seen in **Table 1** and **Figure 4**, the dye intensity from the MO solution decreased with the increment in irradiation time due to the degradation process. The dye removal process nearly achieved at 120 min, with degradation rate of 68.9 % which is an improvised result compared to previous study from Prasannan and Imae (Prasannan & Imae, 2013). This result implied that CQDs can play a significant part in photocatalytic application based on the optical properties that show good optical absorption in the UV and up to near- visible region. Moreover, from the SEM and EDX analysis showing that CQDs synthesis through hydrothermal treatment possess a competent performance in which the presenting elements correspond to the major element that help in photocatalytic activity.

**Table 1.** Percentage of MO removal after 120 minutes photocatalytic activity was carried out

Irradiation time (min)	Percentage of MO Removal (%)
Dark	0.863
0	0.84
20	0.637
40	0.464
60	0.443
80	0.308
100	0.273
120	0.268

**Figure 4:** Percentage of MO removal at different time interval

#### IV. CONCLUSIONS

In short, CQDs were successfully produced using the facile hydrothermal method from a readily available WMR as carbon precursor. Different characterizations analysis that has been conducted indicate the successful preparation of the CQDs with nanometer dimensions, with fascinating surface functional group that are useful in photocatalytic application. Finally, the prepared CQDs appealed to be sufficiently worthy of every recognition due to its value in green synthesis production, high solubility and have unique photoluminescence property that can enhance photocatalytic activity.
